- 1. The female gonads (the **ovaries**)
- 2. the uterus
- 3. the fallopian tubes.
- The ovaries have two functions:
 - 1. oogenesis
 - 2. secretion of the female sex steroid hormones
 - Progesterone
 - estrogen.

The ovary

- The ovary has three zones:
 - 1. The **cortex** is the <u>outer</u> and <u>largest</u> zone. It is lined by <u>germinal</u> <u>epithelium</u> and **contains all of the oocytes**, each of which is <u>enclosed in a follicle</u>. The ovarian follicles are also responsible for **steroid hormone synthesis**.
 - 2. The **medulla** is the <u>middle zone</u> and is a **mixture** of cell types.
 - 3. The **hilum** is the <u>inner zone</u>, through which **blood vessels and lymphatics pass.**
- The ovarian steroid hormones have both paracrine and endocrine functions.
- <u>Paracrine: Locally</u> (within the ovaries) the ovarian steroid hormones <u>support the development of the ova.</u>
- <u>Endocrine: Systemically</u>, the ovarian steroid hormones <u>act on a variety</u> <u>of target tissues</u> including **uterus**, **breast**, and **bone**.
- The functional unit of the ovaries is the **single ovarian follicle** (= **one germ cell surrounded by endocrine cells**).

Functions of the ovarian follicle

- Provides **nutrients** for the developing oocyte
- Releases the oocyte at the proper time (ovulation)
- Prepares the vagina and fallopian tubes to aid in <u>fertilization</u> of the egg by a sperm
- Prepares the lining of the uterus for implantation of the fertilized egg
- Maintains steroid hormone production for the fetus until the placenta can assume this role.

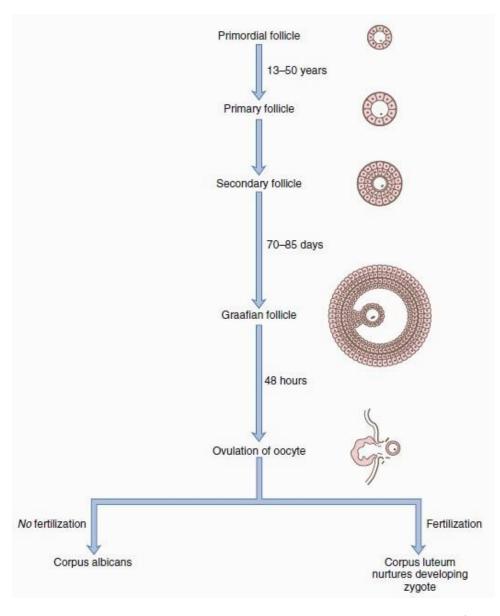

<u>Oogenesis</u>

- In the developing ovaries → primordial germ cells produce oogonia by mitotic divisions until gestational weeks 20-24.
- At <u>gestational weeks 8-9</u> → some of the oogonia enter the prophase of meiosis and become primary oocytes.
 - ▶ 6 months after birth → all oogonia have become oocytes.
- The oocytes remain in a state of suspended prophase.(that's related to the High level of cyclic AMP and MAPK pathway)
- We start off oogensis with 7 million oogonia. but, there is an attrition of some oocytes. (apoptosis of oocytes)
- Just to know: MAPK pathways relay, amplify and integrate signals from a diverse range of stimuli and elicit an appropriate physiological response including cellular proliferation, differentiation, development, inflammatory responses and apoptosis in mammalian cells

Development of ovarian follicles

First stage:

- > It parallels the prophase of the oocyte.
- It lasts many years (13-50 years).
- As the primary oocyte grows, the granulosa cells proliferate and nurture the oocyte with nutrients and steroid hormones.
- The primordial follicle develops into a primary follicle, theca interna cells develop, and granulosa cells begin to secrete fluid.
- ➤ No follicle progresses beyond this first stage in prepubertal ovaries.

<u>Development of ovarian follicles – Second stage</u>

- It takes place over a period of 70–85 days and is present only during the reproductive period.
- During each menstrual cycle, a <u>few follicles enter this sequence</u>.
- A fluid <u>containing steroid hormones</u>, <u>mucopolysaccharides</u>, <u>proteins</u>, and **FSH** accumulates in a <u>central area of the follicle</u> called the **antrum**.
- The steroid hormones reach the antrum by direct secretion from granulosa cells. The granulosa and theca cells continue to grow.
- At the **end of the second stage**, the follicle is called a **graafian follicle** and has an average diameter of 2–5 mm.

Development of ovarian follicles – Third stage

- It occurs **5–7 days after menses** (menses marks the end of the previous cycle and means the flow of blood).
- A <u>single graafian follicle achieves dominance</u> over its cohorts, and <u>the cohorts regress</u>.
- Within 48 hours (after 5-7 days), the dominant follicle grows to 20 mm in diameter.
- On day 14 of a 28-day menstrual cycle, ovulation occurs and the dominant follicle ruptures and releases its oocyte into the peritoneal cavity.
- At this time, the first meiotic division is completed and the <u>resulting</u> <u>secondary oocyte</u> enters the nearby fallopian tube, where it begins the second meiotic division.
- In the fallopian tube, if <u>fertilization by a sperm occurs</u>, the <u>second</u> meiotic division is completed, producing the haploid ovum (1n) with 23 chromosomes.

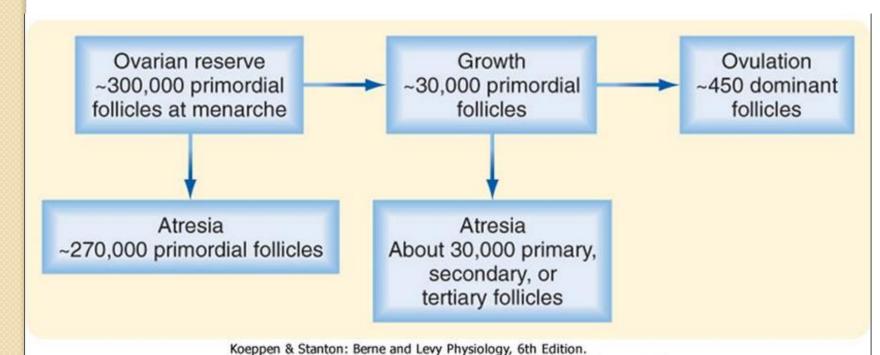

Development of ovarian follicles –in other way

- هون التقسيمة مختلفة عن ال stages
- <u>Preantral phase/follicle:</u> primoridal follicle + primary follicle + secondary follicle.
- Parallels to stage 1 & 2
- Those follicles :
- 1) do not contain fluid filled antrum.
- Their development is **gonadotropin independent**. Are not influenced by Hypothalamic-pituitary axis hormones.
- <u>Eantral phase/follicle:</u> the same of graafian follicle, also called third follicle
- Parallels to stage 3
- Each menstruation, one of these follicle will be ovulated
- If there is fertilization, this follicle will complete the second mitosis

- The <u>residual elements</u> of the ruptured primary follicle form the **corpus** luteum.
 - Composed primarily of **granulosa** cells, but also of **theca** cells, **capillaries**, and **fibroblasts**.
 - It synthesizes and secretes steroid hormones, which are necessary for implantation and maintenance of the zygote. So it must still for 14 (+/- 2) days, and the life span may be elongated to 9 month if fertilization occure..... If the corpus luteum life span is less than 14 days, that can lead to infertility.
- If fertilization does occur \rightarrow the corpus luteum will secrete steroid hormones until the placenta assumes this role, later in pregnancy.
- If fertilization does not occur, the corpus luteum regresses during the next 14 days (the second half of the menstrual cycle) and is replaced by a scar called the corpus albicans.
 - corpus luteum regression occurs due to **prostaglandins** ($PGF_{2\alpha}$) "limiting factor"

From Berny & Levy page 800:

- The primordial follicles represent the ovarian reserve of follicles
- This reserve is reduced from a starting number of about 7 million to less than 300,000 follicles at reproductive maturity.
- Of these, a woman will **ovulate about 450** between **menarche** (<u>first menstrual cycle</u>) and **menopause** (<u>cessation of menstrual cycles</u>).
- <u>At menopause</u>, less **than 1000 primordial follicles are left in the ovary.** (Primordial follicles are lost primarily from death as a result of follicular atresia.)

Copyright © 2008 by Mosby, an imprint of Elsevier, Inc. All rights reserved

- the ovarian follicular reserve represents a <u>fixed finite number</u>, the rate at which <u>resting primordial follicles die or begin to develop (or both)</u> will **determine the reproductive life span** of a woman.
- Age at the onset of menopause has a **strong genetic component** but is also **influenced by environmental factors**.
- For example, <u>cigarette smoking</u> significantly **depletes the ovarian reserve**. How?

An overly **rapid rate of atresia** or **development** will <u>deplete the</u> <u>reserve</u> and **give rise to premature ovarian insufficiency.**

<u>During the early weeks</u> of gestation, <u>we do not want antimüllerian</u> <u>hormone</u>. However, <u>we do need it later</u> on as that level (1-3ng/ml) is needed to maintain the ovarian reserve. How?

This is because it counteracts the effects of FSH hormone (which tries to push oocytes into the growth phase for ovulation).

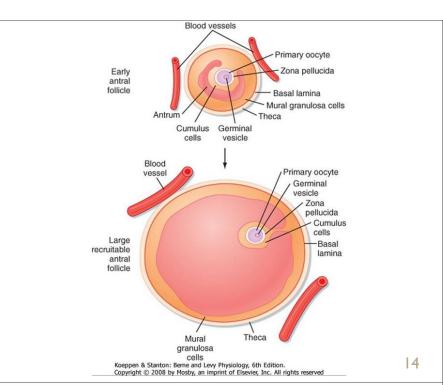

• <u>To stop the recruitments of follicles in large amounts by FSH</u>, we need **antimüllerian hormone**. Otherwise, "ovarian failure" happens due to FSH.

Notes:

- Sperms bind to species specific receptor (each mammalian has its own receptors) which triggers the oocyte to start the second meiotic division.
- **Zona pellucida** around the oocyte is **responsible** for <u>forming the species</u> <u>specific receptor.</u>
- There is no duct for ovaries allows the follicle to leave from during ovulation.
- The ova/dominant follicle grows in size. as a result, the <u>wall of the ovaries pinches</u> to form a hole <u>from which the dominant follicle can leave from</u>, by triggering an inflammatory cascade (This hole means there is an injury in this site.)
- the hole will be repaired later by rapid epithelial cell proliferation and scar formation.
- This is repeated each cycle.

From Berny & Levy page 801:

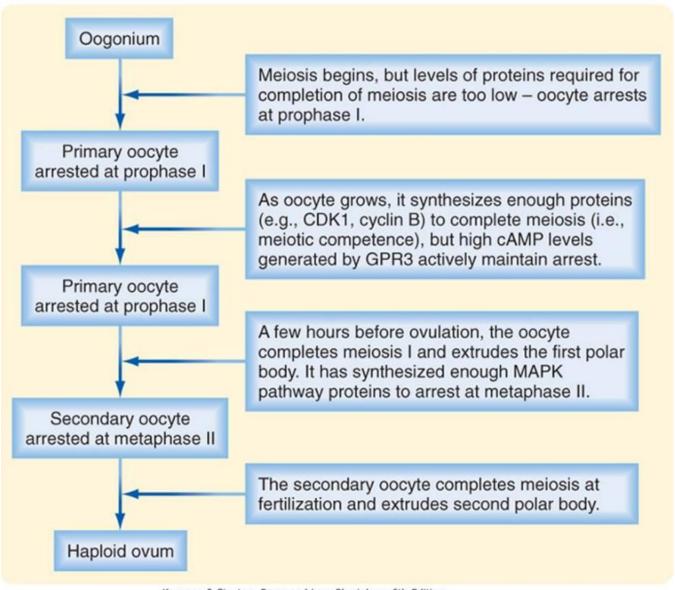

- Mural granulosa cells (also called the <u>stratum granulosum</u>) form the outer wall of the follicle. The <u>basal layer is adherent to the basal lamina</u> and in close <u>proximity to the outer-lying thecal layers</u>.
- In antral phase, become highly **steroidogenic** and <u>remain in the ovary</u> <u>after ovulation</u> to **differentiate** into the **corpus luteum**.
- Cumulus cells are the inner cells that <u>surround the oocyte</u> (also referred to as the <u>cumulus oophorus</u> and <u>corona radiata</u>).
- The **innermost layer** of cumulus cells **maintains gap** and **adhesion** junctions with the oocyte.
- Cumulus cells are <u>released with</u> the oocyte (collectively referred to as the **cumulus-oocyte complex**) during the process of ovulation.
- Cumulus cells are crucial for the ability of the fimbriated end of the oviduct to "capture" and move the oocyte by a ciliary transport mechanism along the length of the oviduct to the site of fertilization.

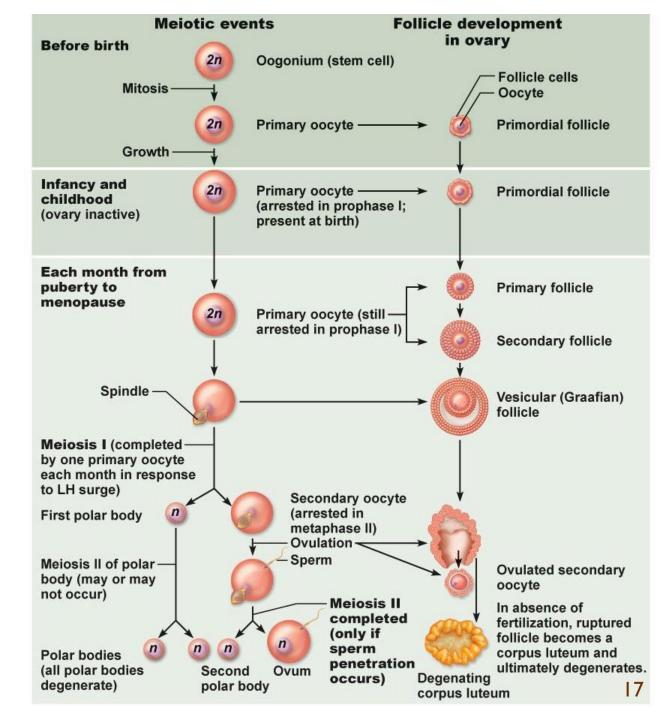

Summary of ovarian follicle trajectory

- The ovarian follicle is the functional unit of the ovary, and it performs both gametogenic and endocrine functions. A histological section of the ovary from a premenopausal cycling woman contains follicular structures at many different stages of development. The life history of a follicle can be divided into the following stages:
- 1. Resting primordial follicle
- 2. Growing preantral (primary and secondary) follicle
- 3. Growing antral (tertiary) follicle
- 4. Dominant (preovulatory, graafian) follicle
- 5. Dominant follicle within the periovulatory period
- 6. Corpus luteum (of menstruation or of pregnancy)
- 7. Atretic follicles

Summary:

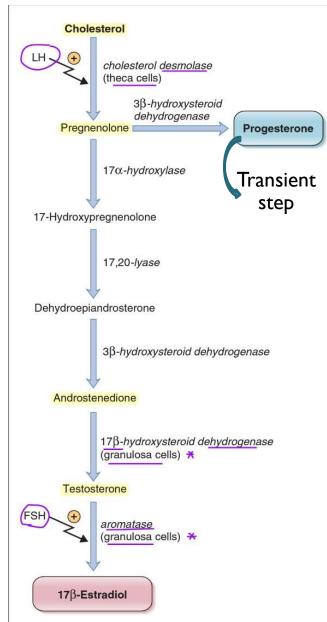

Summary:

Synthesis and secretion of estrogen and progesterone

- Theca cells produce <u>progesterone</u>
 (stimulated at the first step by LH).
- Theca cells also <u>synthesize androstenedione</u>
 → androstenedione diffuses to the nearby granulosa cells, which contain
 - 17β-hydroxysteroid dehydrogenase,
 which converts <u>androstenedione</u> <u>to</u>
 testosterone
 - Aromatase or CYP19, which converts testosterone to 17β-estradiol (stimulated by FSH).
 - Later on, granulosa cells produce other hormone called Inhibin...
 - Low levels of <u>estrogen</u> and <u>inhibin</u> negatively feed back on FSH secretion.. thereby contributing to <u>selection</u> of the <u>follicle</u> with <u>the most FSH-responsive</u> cells.
